#### Eureka to Howardsville - August 1998

The California Gulch study reach ended just downstream from Animas Forks (fig. 1).

There was a substantial part of the Upper Animas subbasin from that point to just upstream from Eureka Gulch that was not covered by a mass-loading study. Load information for the upstream end of the Eureka to Howardsville tracer study gives a net account of the loading in this unstudied reach, but does not include detail about any sites in the reach.

A main objective of the tracer study from Eureka to Howardsville was to quantify the flow and metal loading through a braided reach between Eureka Gulch and Minnie Gulch (fig. 61). This section of the study reach could act as a source or a sink for metals in the Upper Animas River, and quantification with a mass-loading study would help to define how the braids affect loads downstream. Details of the mass-loading study for this reach have been published by Paschke and others (in press). The following discussion summarizes findings of that report.

#### Study Area and Experimental Design

The mass-loading study for Eureka to Howardsville, called the Eureka study reach in this report, covered a 6,128 m section of the Upper Animas subbasin, starting upstream from Eureka Gulch, and continuing to a point just downstream from the gaging station near Howardsville (figs. 1 and 66). This distance was divided into 32 stream segments, 15 of which bracketed 18 sampled inflows along the study reach. The largest of these inflows were Eureka Gulch (EI-347), Minnie Gulch (EI-2420), Maggie Gulch (EI-3450), and Cunningham Gulch (6558), along with several seeps and springs. Site designations for stream and inflow samples are listed with other identifying information in table 22.

Abandoned mines and prospects exist along the study reach; the discharge from the Pride of the West Mill and tailings area near Howardsville (EI-6438) was one of the most visually significant for its iron staining in the stream (see Martin and others, Chapter 4G this volume). In general, the rocks on both sides of the canyon have propylitic alteration, but there also are areas of quartz-sericite-pyrite alteration (Bove and others, this volume). Stream elevation ranged from approximately 9,800 ft at the injection site to 9,640 ft downstream from Cunningham Gulch. Geology of the basin is described in Yager and Bove (this volume) and Bove and others (this volume).

## Discharge

Sodium chloride was used as the tracer for this study reach. The injectate solution had a chloride concentration of 101,100 mg/L, and was injected at a rate of 1.784 L/min, starting 1002 hours on 12 August 1998, and ran continuously until 1930 on 14 August 1998 (Paschke and others, in press). Background concentrations of chloride were low in comparison to the injected concentrations (fig. 67). Chloride decreased systematically downstream from the injection, indicating those stream segments receiving inflow. Discharge increased by 60.3 ft<sup>3</sup>/s along the study reach, and stream segments that contained sampled inflows accounted for 85 percent of this increase. Those segments that had no sampled inflows contributed 15 percent of the increase.

#### Figure 67 near here.

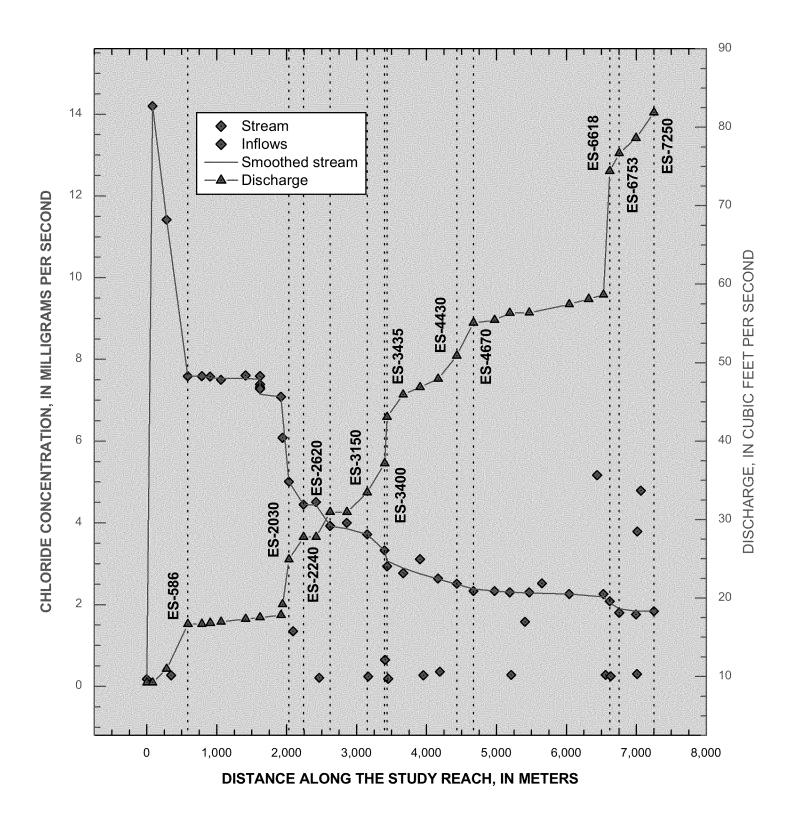

Figure 62. Variation of chloride concentration and calculated discharge, Upper Animas River from Eureka to Howardsville, Coloardo, August 1998.

Cunningham Gulch (segment ES-6618) was the largest tributary inflow, accounting for 11.4 ft<sup>3</sup>/s, or 19 percent of the flow. The change in flow through the braided reach of stream (fig. 61) is accounted for at segment ES-2030, downstream from where the braids come back together (fig. 61). The increase at that point was 8.5 ft<sup>3</sup>/s, or 14 percent of the increase in flow. Eureka Gulch (ES-586) contributed 5.8 ft<sup>3</sup>/s or about 10 percent of the increase. Maggie Gulch (ES-3435), the area near the Kitty Mack tailings (ES-3400), Minnie Gulch (ES-2240), and Hematite Gulch (ES-6753) each contributed greater than 5 percent of the flow.

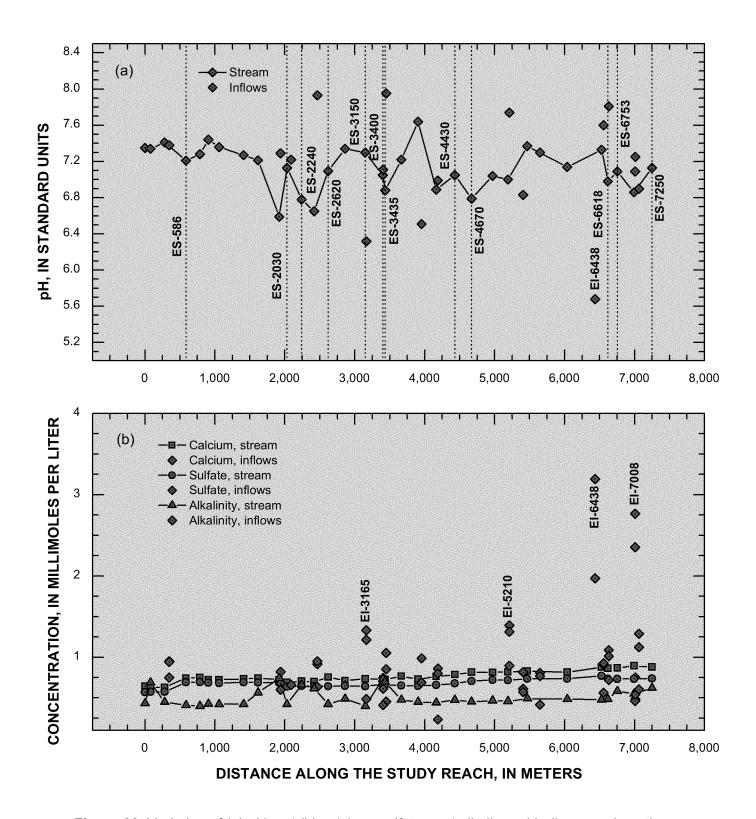

## **Characterization of Synoptic Samples**

Along the study reach, pH ranged from about 6.6 to 7.6; but there was no systematic spatial trend of pH (fig. 68a). Only the inflow from the tailings near Howardsville (EI-6438) had a pH value less than 6.0. Throughout the study reach, the dominant major ions were calcium and sulfate; alkalinity was about half of the sulfate concentration (fig. 68b). Like values of pH, there was not much variation in these major ion concentrations.

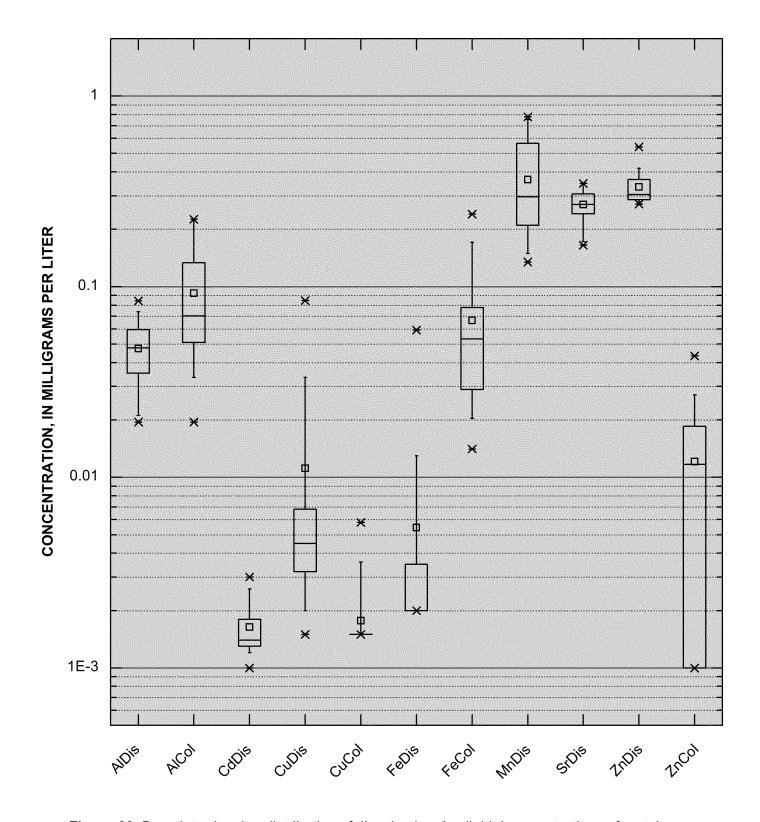

## Figure 68 near here.

Despite the consistent major-ion concentrations along the study reach, concentrations of metals did vary. Aluminum, copper, manganese, strontium, and zinc were elevated (fig. 69). Lead and nickel concentrations generally were less than detection. Manganese concentrations ranged up to 0.78 mg/L and had a median of 0.30 mg/L. Median concentration of zinc also was 0.30 mg/L (fig. 69). Colloidal concentrations of aluminum and iron were greater than dissolved concentrations, which was consistent with the relatively high pH of the study reach (figs. 68a and 69). The median concentration of colloidal iron was 0.049 mg/L; while the median dissolved concentration was less than detection, indicating the dominance of the colloidal phase. Colloidal concentrations of copper and zinc also were measurable, but generally less than dissolved concentrations. The median concentration of colloidal copper was less than detection, but of colloidal zinc was 0.011 mg/L.

# Figure 69 near here.

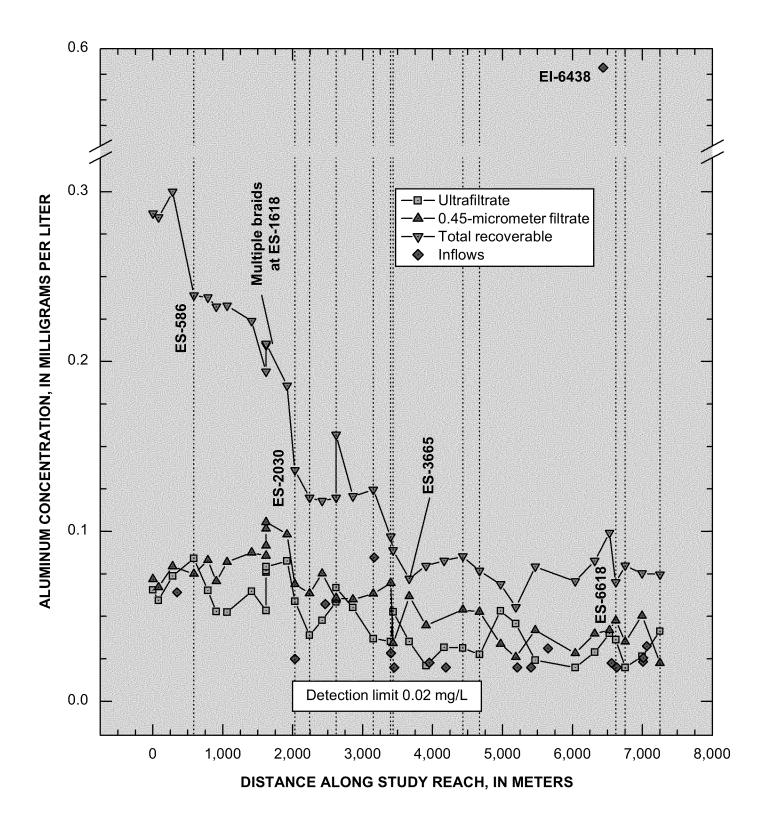

**Figure 68**. Variation of (a) pH and (b) calcium, sulfate, and alkalinty with distance along the study reach, Upper Animas River, Eureka to Howardsville, Colorado, August 1998.

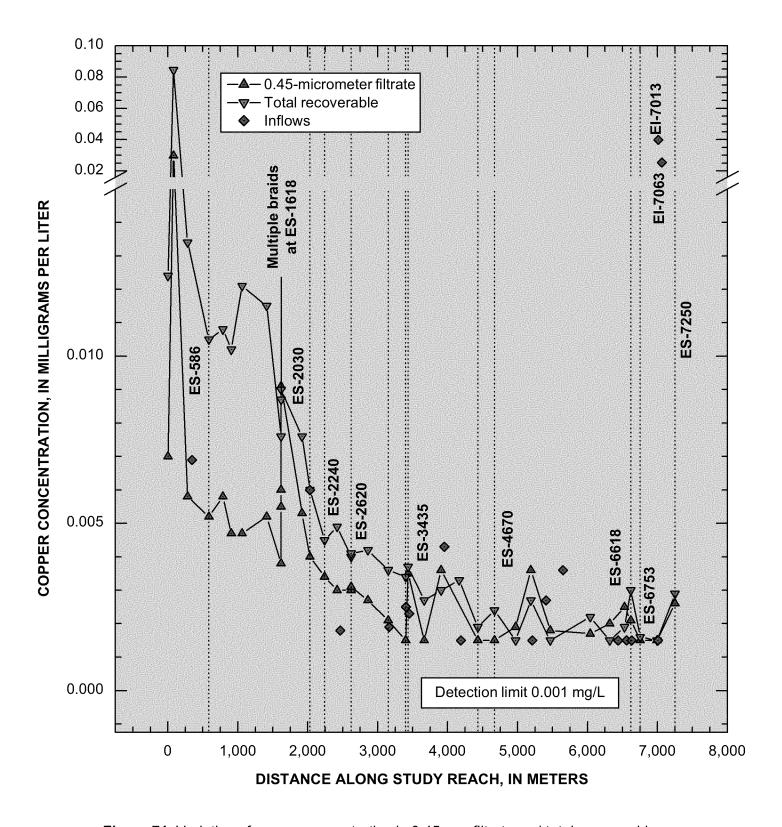

**Figure 69**. Box plots showing distribution of dissolved and colloidal concentrations of metals in synoptic stream stamples, Upper Animas River, Eureka to Howardsville, Colorado, August 1998.

Colloidal concentrations of aluminum and copper mostly occurred at the beginning of the study reach, and were less predominant after the braided reach of the stream (downstream from ES-2030, figs. 70 and 71). The highest inflow concentration of aluminum occurred in the discharge near Howardsville (EI-6438). The last two sampled inflows, EI-7013 and EI-7063, had the highest inflow concentrations of copper. Unlike any of the other metals, copper concentrations, for both the 0.45-µm filtrate and the total-recoverable concentrations were highest at ES-80, rather than at EW-0, at the beginning of the study reach. This could be due to a dispersed, subsurface inflow with high copper concentration in the segment ES-80, which is near the old Eureka Mill.

Figures 70 and 71 near here.

**Figure 70**. Variation of aluminum concentration in ultrafiltrate, 0.45-μ m filtrate, and total-recoverable samples with distance along the study reach, Upper Animas River, Eureka to Howardsville, Colorado, August 1998.

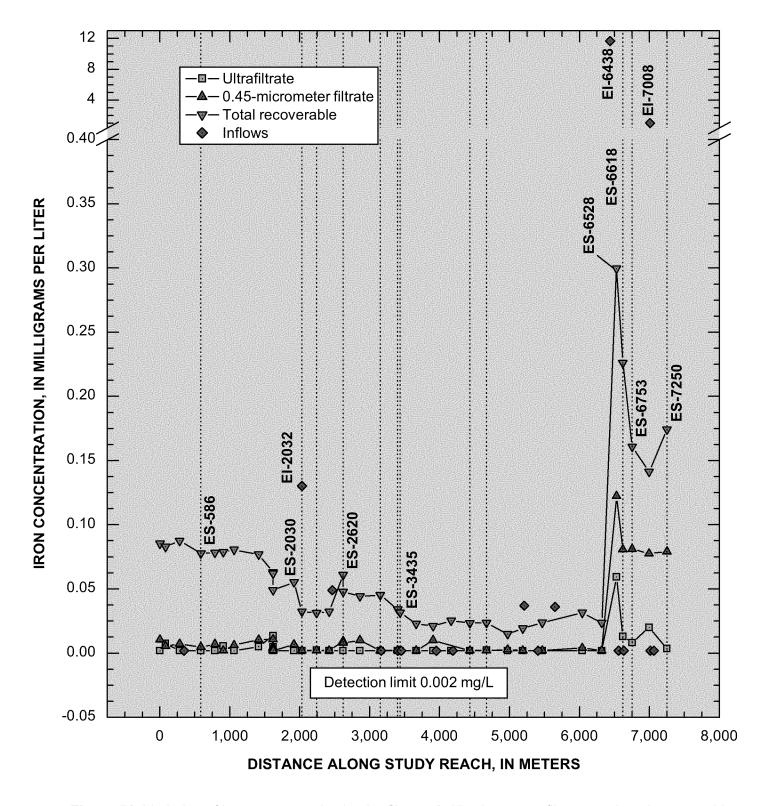

**Figure 71**. Variation of copper concentration in  $0.45-\mu$  m filtrate and total-recoverable samples with distance along the study reach, Upper Animas River, Eureka to Howardsville, Colorado, August 1998.

At the beginning of the study reach, colloidal iron concentrations were relatively high, comparable to colloidal aluminum and copper (fig. 72). However, colloidal iron concentrations were much higher downstream from the inflow at EI-6438, which had visible iron staining, along the left bank all the way to Cunningham Gulch (EI-6558). Note that the total-recoverable and 0.45-µm filtered concentrations increased substantially with this inflow, but the increase of ultrafiltrate iron was much lower. This indicates the effectiveness of the various filter sizes to distinguish dissolved iron in this reach. There could have been some colloidal material in the ultrafiltrate, however, it was much more effective in separating the dissolved and colloidal iron (Kimball and others, 1995).

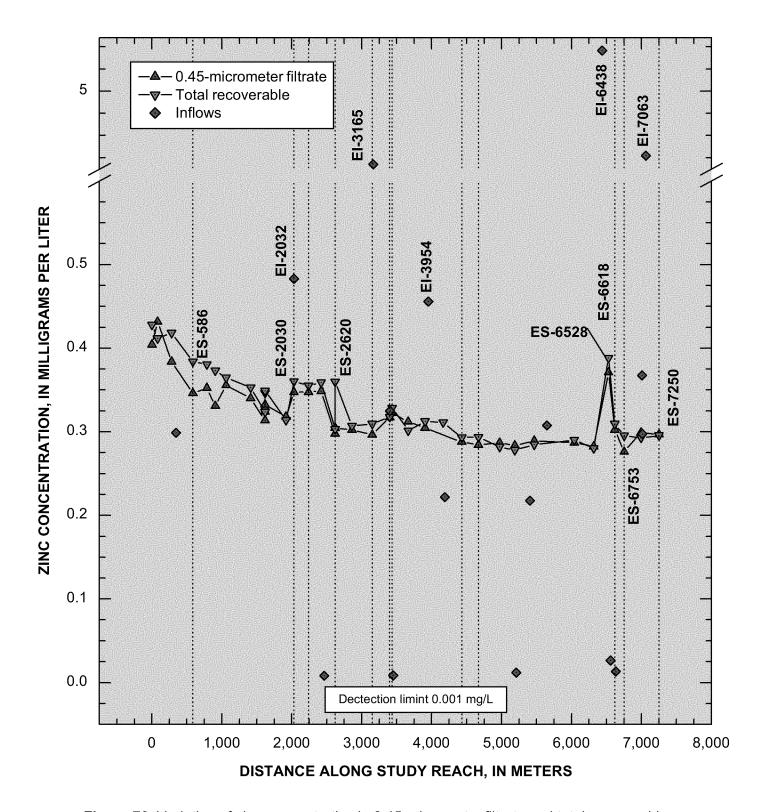

# Figure 72 near here.

The highest instream concentration of zinc occurred at the beginning of the study reach (fig. 73). Through the braided reach, zinc concentration decreased, but then increased downstream from the Forest Queen Mine, downstream from ES-2030. Downstream from Minnie Gulch zinc concentrations remained nearly constant at about 0.3 mg/L until ES-6528, downstream from the inflow draining mill tailings near Howardsville. Several of the ultrafiltrate zinc concentrations were greater than the total-recoverable concentrations, so there could have been some contamination. Thus, the ultrafiltrate concentration is not shown in figure 73.

#### Figure 73 near here.

**Figure 72**. Variation of iron concentration in ultrafiltrate, 0.45-micrometer filtrate, and total-recoverable samples with distance along the study reach, Upper Animas River, Eureka to Howardsville, Colorado, August 1998.

**Figure 73**. Variation of zinc concentration in 0.45-micrometer filtrate and total-recoverable samples with distance along the study reach, Upper Animas River, Eureka to Howardsville, Colorado, August 1998.

Variations in concentration, especially the changes that occur as water moves through the braided reach between Eureka and Howardsville, help to classify stream and inflow samples by means of PCA. Two groups of stream samples and four groups of inflow samples were identified. The biplot indicates the covariance of the solutes; the covariance results from the chemical and physical process affecting the transport and transformation of metals from various sources in the watershed (fig. 74). The median concentration of samples in each group, broken down between stream and inflow samples, is listed in table 23. Stream samples near the top of the biplot have the highest concentrations; these are the most upstream sites, upstream from Eureka Gulch (ES-0 and ES-280). Vectors for copper and aluminum are grouped together because of the decrease in colloidal concentrations through the braided reach; group 1 stream samples had lower concentrations than group 2 stream samples. Metals, including manganese, zinc, cadmium, and iron are grouped with hydrogen ion, or acidity, and the changes among groups of stream samples represent the decreased concentrations of these metals downstream from the braided reach.

Finally, sulfate, magnesium, calcium, and strontium are grouped because of bedrock weathering.

## Figure 74 near here.

Groups of inflow samples plot around the stream samples and represent the compositional end members that result from water-rock interactions in the watershed. Note that most of the inflows in this study reach plot away from higher metal concentrations (indicated by the direction of the arrows). There was only one metal-rich inflow at EI-6438, the drainage from old tailings near Howardsville.

#### **Load Profiles**

Load profiles indicate the nature of changes through the braided reach, whether the changes result from dilution or reaction. A summary of load calculations for this study reach is listed in table 25. There were three general patterns among metal loading profiles along the study reach from Eureka to Howardsville, and these patterns indicate differences among sources and reactions affecting the different metals.

Aluminum (fig. 75) and copper (fig. 76) had similar loading profiles, which were characterized by a large metal load at the beginning of the study reach that decreased through the braided reach. Although there were other locations of aluminum and copper loading within the study reach, they were small in comparison to the loads at the beginning of the study reach. Even though the aluminum concentration decreased substantially along the braided reach (fig. 70), the loss of aluminum load was not as substantial; the decrease in aluminum concentration was mostly due to dilution. The decrease in copper concentration (fig. 71), on the other hand, was due to actual loss of copper load (fig. 76b) through reaction and not due to dilution.

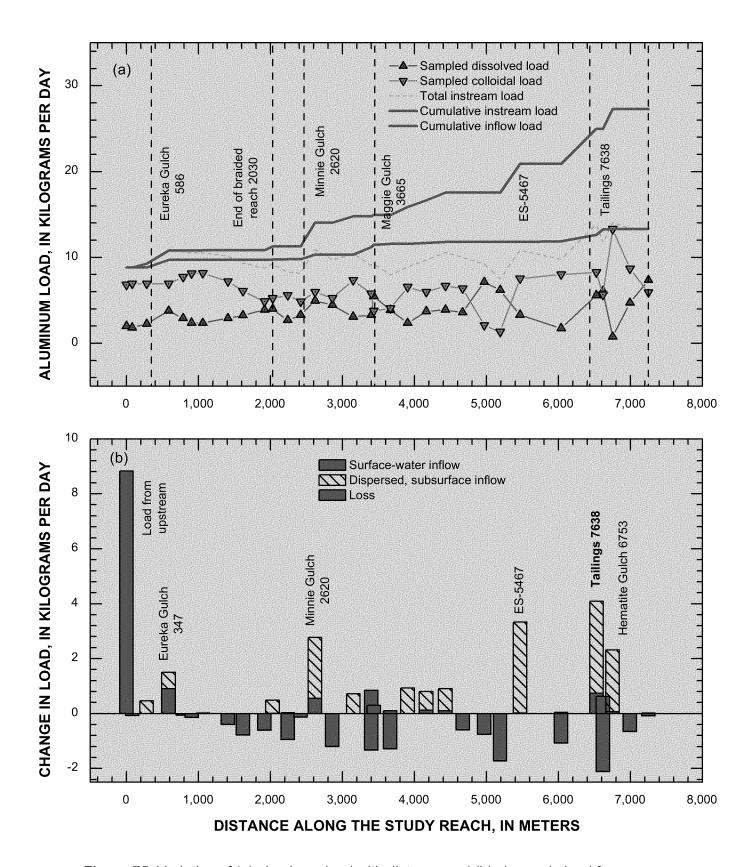

Figures 75 and 76 near here.

Table 25. Summary of load calculations for upper Animas Gulch, Eureka to Howardsville, Colorado, August 1998.

[Al, aluminum; Cd, cadmium; Cu, copper; Fe, iron; Mn, manganese; Ni, nickel; Sr, strontium; Zn, zinc; SO4, sulfate; loads are in kilograms per day.]

**Figure 75**. Variation of (a) aluminum load with distance and (b) change in load for individual stream segments, Eureka to Howardsville, Upper Animas River, Colorado, August 1998.

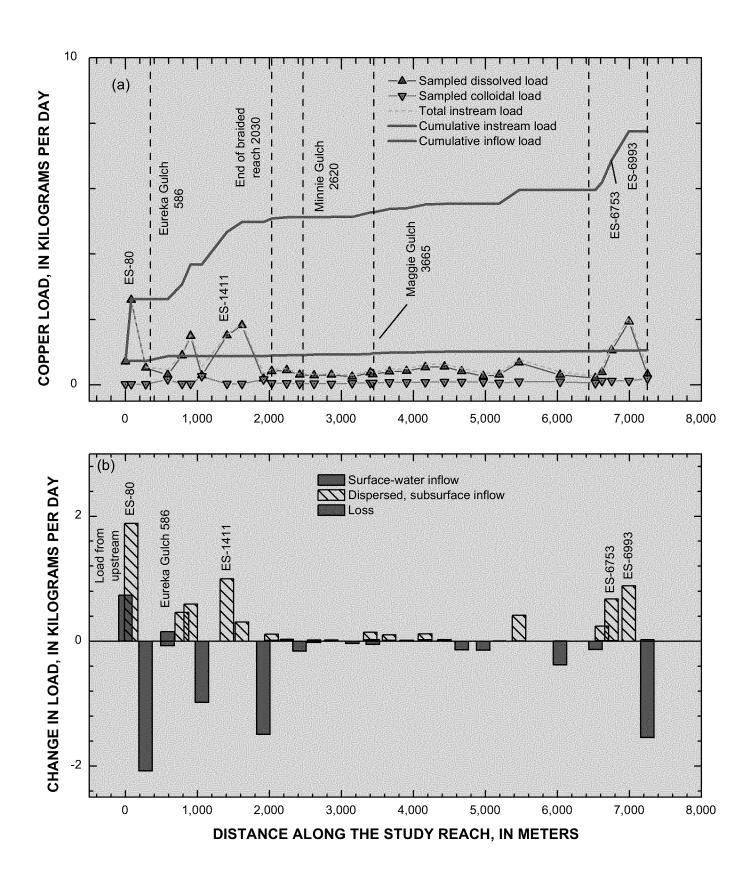

Figure 71. Variation of (a) copper load with distance along the study reach and (b) change in load for individual stream segments.

Although manganese (fig. 72) and zinc (fig. 73) loads are substantial at the beginning of the study reach, both these elements differ from aluminum and copper by having even greater loads contributed within the study reach. For manganese, the greatest load was contributed in the segment including the discharge from old tailings near Howardsville (ES-6528). Most of that load was due to surface-water inflow, but some of it was due to dispersed, subsurface inflow (fig. 72b). Zinc had substantial contributions from several segments along the study reach, but also from the drainage of old tailings near Howardsville (ES-6528). Loads were considerable from the segment at ES-2030, which was the end of the braided reach, and at ES-3400, which contained a large area of the old Kitty Mack tailings. The bar at ES-3400 in figure 73b indicates a surface-water inflow, because there was a right bank inflow that may have been from Otto Gulch on the right bank. The Kitty Mack tailings, however, were on the left bank, and so that inflow likely was subsurface inflow. Zinc also was contributed in the segment at the Howardsville gage, ES-6993, and this was a subsurface inflow.

## Figures 72 and 73 near here.

Iron load (fig. 74) was similar to manganese and zinc because of the large load at ES-6528, draining the old tailings ponds near Howardsville. As in many other tracer-studies, the amount of iron inflows most likely is underestimated because iron is so reactive that a net reaction removes iron from the stream before the net accounting at the downstream site of the segment.

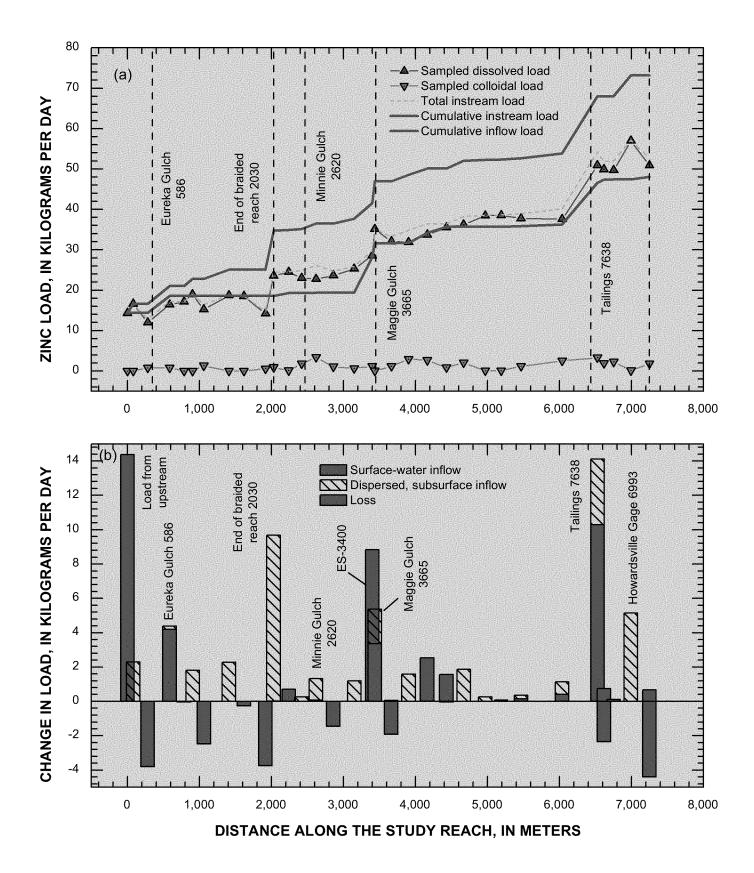

Figure 73. Variation of (a) zinc load with distance along the study reach and (b) change in load for individual stream segments.

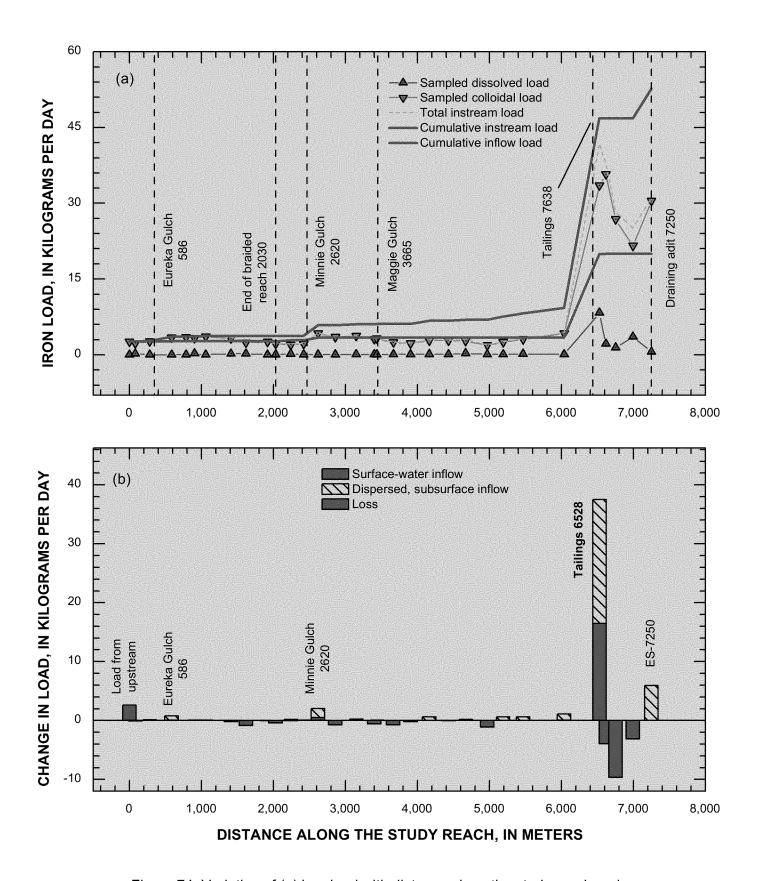

Figure 74. Variation of (a) iron load with distance along the study reach and (b) change in load for individual stream segments.

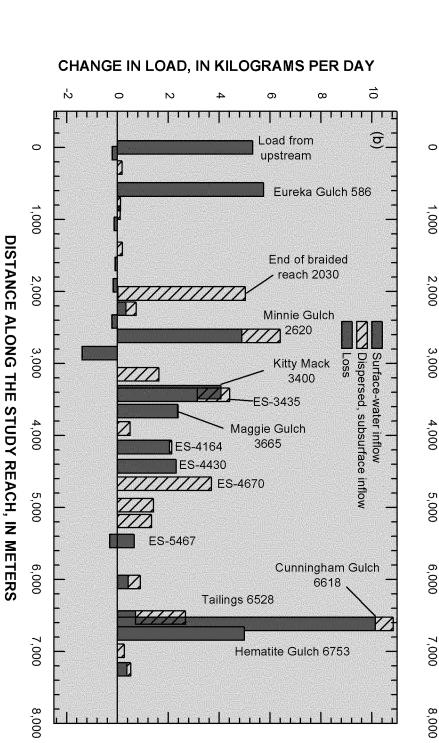

The third pattern of metal loading is represented by strontium (fig. 75) and sulfate (fig. 76). For both these solutes, there were many more sources of loading along the study reach than for the other solutes because their sources were not limited to the ore minerals. For example, Cunningham Gulch (ES-6618) was a major source of loading only for strontium and sulfate, but the tailings drainage near Howardsville (ES-6528) was a relatively minor source (figs 75b and 76b). Another difference for these two solutes is that the majority of the load was surface-water inflow, and not subsurface inflow (table 24). There was some loading by subsurface inflows for sulfate, however, at ES-4670 and ES-4970.

# Figures 75 and 76 near here.

## Principal sources of metal load

There were three locations where most of the metal loading occurred along the Eureka to Howardsville study reach (table 25). For aluminum, copper, zinc, and sulfate the greatest loading was from sources upstream from the study reach, although for copper this load is indicated in the segment at ES-80. Upstream sources were also important for manganese, but the greatest source of iron and manganese was the segment draining the old tailings near Howardsville (ES-6528). This segment also was important for aluminum and zinc. Finally, the last two segments along the study reach, ES-6993 and ES-7250, were important sources of cadmium, copper, iron and zinc. There were more segments that with at least 5 percent of the load for strontium and sulfate than for the other solutes. This pattern is consistent with multiple sources for these two solutes that are more widespread throughout the watershed, and not just confined to those segments most associated with mine drainage.

# Dispersed, Subsurface inflows

Subsurface inflow, which was calculated as unsampled inflow, was responsible for over half the loading for aluminum, cadmium, copper, and iron (table 24). Subsurface inflow was less important for manganese strontium, zinc and sulfate, but did occur for each solute. There were two main locations of subsurface inflow. The segment draining old tailings near Howardsville (ES-6528) was important for aluminum (fig. 70b), iron (fig. 74b), and manganese (fig. 72b). The segment at the end of the braided reach (ES-2030) was important for strontium (fig. 75b) and zinc (fig. 73b). Segments ES-470 and ES-4970 were important for the inflow of sulfate (fig. 76b) and, to a lesser extent, strontium (fig. 75b).

4/16/2002

## Attenuation

Over half of the copper, cadmium, and aluminum loads were removed along the study reach (table 24). As noted for copper and aluminum, much of this attenuation was in the upper part of the study reach, in the braided reach. There was very little attenuation of strontium and sulfate. About 25 percent of the manganese and zinc loads were removed. The 41 percent attenuation for the iron load most likely was an underestimate because only a net reaction was measured for each segment by the tracer study.
